ABSTRACT

The structural nature and thermal stability of amorphous alloys is highly dependent on the method by which they are produced, i.e. their relaxation rate upon cooling. Both bulk samples and metallic glass films of $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ were produced by copper mold casting and direct current (DC) magnetron sputtering onto aluminium substrates, respectively. Comparisons between structural enthalpy, crystallisation pathways, relaxation and crystallisation kinetics of the bulk samples and films were examined by elevated temperature XRD and DSC. Compared with equivalent experiments on the bulk alloy, results for the thin films show distinct differences in structural enthalpy and deviations from the expected crystalline phase evolution, displaying minor peak shifts, failure of some phases to evolve, and variations in the evolution rates.

1 INTRODUCTION

The structural nature and thermal stability of amorphous alloys is highly dependent on the method by which they are produced, i.e. their relaxation rate upon cooling. Both bulk samples and metallic glass films of $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ were produced by copper mold casting and direct current (DC) magnetron sputtering onto aluminium substrates, respectively. Comparisons between structural enthalpy, crystallisation pathways, relaxation and crystallisation kinetics of the bulk samples and films were examined by elevated temperature XRD and DSC. Compared with equivalent experiments on the bulk alloy, results for the thin films show distinct differences in structural enthalpy and deviations from the expected crystalline phase evolution, displaying minor peak shifts, failure of some phases to evolve, and variations in the evolution rates.

2 METHOD

2.1 Master alloy

The master alloy of $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ was produced using high-purity elements of Mg (99.85 wt%), Zn (99.995 wt%), and Ca (99.8 wt%). The alloy was prepared with an in-house induction melting furnace within boron nitride coated graphite crucibles, purged with Ar (99.997 vol.% purity) five times, and protected with a circulating Ar atmosphere. Alloy homogeneity was ensured by heating and cooling through a cycle of 700°C, 385°C, 650°C, 385°C, 650°C to a casting temperature of 500 °C and 450°C for injection and gravity casting respectively. Bulk amorphous $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ rods of nominal 2.5mm diameter and plates of nominal 1.2mm thickness were produced by copper mold injection casting. The 25.4mm diameter targets were prepared from cylindrical copper mold gravity castings sectioned to thicknesses of 3.25mm. All samples and targets were stored under Ar when not being examined or used.

2.2 DC magnetron sputtering

Films were produced from an in-house DC magnetron sputtering facility with Ar working gas (99.997 vol.% purity). The power was 15W, typical voltage of 285 – 325V, nominal chamber pressure of 1 bar, substrate temperature of 25°C, and Ar flow of 3.01 SCCM. Films were deposited directly onto to Al DSC lid substrates. Depositions were for a period of 35 minutes at an estimated rate of 0.8nm/s.

2.3 Stylus profiler analysis

Nominal film thickness was measured by a stylus profiler (Dektak 2A, Bruker, Germany). A glass slide was placed under the substrates within the sputtering chamber, allowing the substrates to act as a mask. Profile measurements were taken by measuring the height difference between the bare glass and the film coated glass. This film thickness was used to estimate the sputter deposition rate.

2.4 EDS analysis

Alloy composition and homogeneity were confirmed by SEM-EDS (S3400-N, Hitachi, Japan; Nova NanoSEM 230/450, FEI, The Netherlands). Hyper-maps were collected with an accelerating voltage of 15 – 20kV, a probe current of 50 μ A, counts of 5000 kps or better, dead time less than 20 %, and working distance was 10mm.

2.5 DSC characterization

Isochronic DSC (204 F1 Phoenix, Netzsch, Selb, Germany) was carried out in Al crucibles under a protective Ar atmosphere (99.997 vol.% purity). Scans were performed at heating rates (β s) of 5 to 100K/min.

Isothermal relaxation DSC was performed by heating samples at 20K/min to the desired annealing temperature, holding for desired time, and Ar quenching to room temperature.

For annealed XRD the samples were heat treated in the DSC by heating to the desired temperature at 20K/min followed by Ar quenching to room temperature.

2.6 XRD characterization

Annealing XRD (Empyrean, PANalytical, Cu K_{α} X-ray source, $\lambda = 1.541\text{\AA}$) was performed at room temperature. With a generator voltage 45kV, tube current 40mA, scan step size 0.0262606, and time per step of 397.29.

Dynamic XRD (D8, Bruker, Cu K_{α} X-ray source, $\lambda = 1.541\text{\AA}$) was performed by raising temperature at a rate of 20K/min and performing scans *in situ*. The first scan was performed at 35°C, then 75°C, after which temperature was raised in 5°C increments until reaching a final temperature at 185°C. The 2θ scans from 31 – 60° were completed within 1092sec

(18min, 12sec) to minimise the effects of recrystallisation during the experiment. With a generator voltage 45kV, tube current 100mA, scan step size 0.02, and time per step of 134.4.

3 RESULTS

3.1 Alloy composition

From the 35 minute depositions a nominal film thickness of $1.64 \pm 0.48\mu m$ was obtained, giving a deposition rate of approximately $0.81 \pm 0.22nm/s$. The substrate temperature within the chamber was found to rise $2.9 - 3.5^{\circ}C$, significantly less than the expected 20K suggested by similar setups [1], see Figure 1.

Figure 1: (a) Box and whisker plot of the measured film thicknesses from depositions. (b) Box and whisker plot of the calculated deposition rates achieved. (c) Box and whisker plot of substrate temperature rise.

EDS analysis shows good agreement in the nominal composition for both the bulk and film $Mg_{65}Zn_{30}Ca_5$, see Table 1.

Table 1: EDS composition of bulk and film $Mg_{65}Zn_{30}Ca_5$ in atomic weight percent.

EDS Analysis	Bulk (at%)	Film (at%)
Mg	64.85 ± 3.18	62.92 ± 3.24
Zn	29.55 ± 0.82	31.17 ± 0.95
Ca	5.60 ± 0.17	5.91 ± 0.19

3.2 DSC

3.2.1 Isochronic DSC

Isochronic DSC was performed on the bulk and film $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ to examine the thermal properties. The bulk alloy was relaxed at 120°C for 10 minutes before DSC measurements to ensure the T_g was clearly visible. The film was not relaxed as unlike the bulk the loss in free volume from relaxation would be significant and make differences between the samples much more difficult to observe [source needed???].

The bulk $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ was examined at heating rates (β s) of 5, 10, 15, 20, 30, 40, 60, 80, and 100 K/min to observe changes in the T_g and the T_x s with β . As expected greater β resulted in greater signal strength, exothermic peaks shifting to higher start temperatures, and an increase in thermal lag resulting in later exothermic finish temperatures and curve convolution. With this convolution the T_g and T_{x1} remained clearly visible for all β s, but $T_{x2,4,5}$ were only visible at low β s, and T_{x3} was not clear at any β , see Figure 2. fig:DSC_vHeatingRate_Bulk

The film was examined at β s of 15, 20, 30, 40, 60, 80, and 100 K/min . The lower β s of 5 and 10 K/min were not utilised owing to the lower film signal compared to the bulk. The reduced signal was likely from the low mass of the film, about $\frac{1}{10}$ that of the bulk. The film showed the expected variable relationships with increasing β as observed in the bulk. The signal intensity increased at a compatible rate to bulk up until β s of 80 and 100 K/min . These final two β s showed great increases in the signal intensity. The exothermic peaks all convoluted together making many of the thermodynamic events difficult to observe at all β s. It also appeared that all exothermic events shifted to lower temperatures as compared to the bulk. The film T_g and T_{x1} s were less defined than for the bulk, but could still be identified for all β s. For all β s the T_{x2-5} onsets could not be easily identified, see Figure 3. fig:DSC_vHeatingRate_Film

3.2.2 Fragility

Using the isochronic DSC data the fragility (m) of the $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ system could be established for both the bulk and film. Numerical solutions where used to fit the DSC variant of the Vogel–Fulcher–Tammann (VFT) relationship for β [2]. Busch1998

$$\beta^{-1} = \tau_0 e^{\left(\frac{D^*T_0}{T_g - T_0}\right)} \quad (1) \quad \text{equ:VFT}$$

Where τ_0 is a pre-exponential factor, D^* is the liquid fragility parameter, and T_0 is the VFT temperature where the barrier to flow becomes infinite.

The m could then be calculated from Equation 2 [3, 4].

$$D^* = 590/(m - 16) \quad (2)$$

Using these two equations for the bulk it was found $\beta^{-1} = 1.338E - 16e^{5274(\frac{1}{T-T_0})}$ with an Adj. $R^2 = 0.972$. This gave a $D^* = 20.4$, and a $m = 44.9$. The film was fitted to $\beta^{-1} = 5.921E - 11e^{2766(\frac{1}{T-T_0})}$ with a lower confidence of Adj. $R^2 = 0.861$, likely owing to the reduced number of data points. This gave a $D^* = 10.0$, and $m = 75.0$, see Figure 4.

3.3 DSC deconvolution

3.3.1 Onset determination

Numerical solutions were used to deconvolute the isochronic DSC data so the various T_x onsets could be accurately determined. This numerical fitting utilised a summation of skewed Gaussian curves to fit a target curve corresponding to the original data; as is a common method [5–9]. This fitting summation takes the form of Equation 3.

$$f(x) = \sum_{n=i}^n h_i e^{-\left(\frac{(x - T_i)^2}{(2c_j)^2}\right)} \quad (3)$$

Where h is the magnitude of the enthalpy peak, T is the temperature at the enthalpy peak centre, and c is the Gaussian RMS width.

The final deconvolved solutions of this fitting for both the bulk and film are shown in Figures 5 and 6 respectively. These results are tabulated in Table 2 for the bulk and Table 3 for the film. Tables 2 and 3 are also plotted together in Figure 7 with the bulk shown in black and the film in red. Note T_g and T_{x1} are obtained from the original raw data, not the deconvolution.

It is worth noting the deconvolution fitted 5 crystallisation events for the bulk $Mg_{65}Zn_{30}Ca_5$, but only 3 events for the film. This occurred because the bulk had 5 well defined events, whereas the film was largely convoluted together. Thus unique solutions could not be obtained for the lesser T_{x2} and T_{x4} events of the film.

3.3.2 Reaction enthalpy

The deconvolution fits were integrated to find the area under each curve. This information provides the specific enthalpy (h) of the crystallisation formation of each phase. These energies are presented in Tables 4 and 5 for the bulk and film respectively. Figure 8 shows the T_x onsets and specific enthalpy (h) for both the bulk and film plotted together.

From Tables 4 and 5, and Figure 8 it can be seen most of the crystallisation formation energy is needed to form the 1st, 3rd, and 5th phases (i.e. $T_{x1,3,5}$). With these three phases accounting for approximately $73 \pm 7\%$ of the bulk crystallisation energy. The total crystallisation energy of these three bulk phases is also similar to the total energy for the films. Demonstrating that the bulk requires more energy to crystallize than the films.

3.3.3 Relaxation enthalpy

For next paper on relaxation / rejuvenation.

3.4 XRD

3.4.1 Annealing XRD

The crystallisation events observed and deconvoluted from the DSC were further examined with annealing XRD. Both the bulk and film were heat treated by annealing to 120, 140, 145, 170, 200, 250, 290, and 320°C before XRD. This allowed for the location of the T_g and T_x s to be confirmed as well as for the crystallisation phases to be identify.

From these experiments 5 previously observed crystallisation phases of the MgZnCa system [10–14] were characterised in the bulk and film $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$. This allowed the

crystallisation process of $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ from the fully amorphous glass to fully crystalline metal to be identified as;

The annealing XRD results are shown in Figures 9 and 10 for the bulk and film respectively. In these figures each phase is identified with a tracer at the temperature it was most strongly observed. Note the Al substrates peaks have been faceted in Figure 10 as to not dwarf the other peaks.

In Figures 9 and 10 it can be observed that $\text{Mg}_{51}\text{Zn}_{20}$ comes out at lower temperature in the film compared to the bulk, while the other phases nucleate and grow at similar rates for both the bulk and film. The temperature each phase is first and last observed are tabulated in Table 6.

Table 6: Temperatures at which each crystallisation phase is first observed and last observed in the annealing XRD for both the bulk and film. All temperatures are in °C.

Phase	Bulk		Film	
	First Temp	Last Temp	First Temp	Last Temp
Glass	35	200	35	200
$\text{Mg}_{51}\text{Zn}_{20}$ [10, 13]	170	200	140	200
Mg	170	320	140	320
$\text{Ca}_2\text{Mg}_5\text{Zn}_5$ [10, 14]	200	250	200	250
MgZn [13]	250	250	250	250
$\text{Ca}_2\text{Mg}_5\text{Zn}_{13}$ [10–12]	290	320	290	320

3.4.2 Dynamic XRD

The annealing XRD was useful for identifying the crystal phases present, but not many difference between the evolution rates of the bulk or film could be observed. Thus samples were subjected to dynamic XRD over their most active 2θ range of $31 - 60^\circ$ to observe changes *in-situ*. This allowed the crystallisation to be actively observed over the range of $35 - 185^\circ\text{C}$, showing how phases evolved over time as the temperature was raised in 5°C increments.

The dynamic XRD data shows that many phases seen in the bulk nucleate at different temperatures, are not observed as strongly, or fail to nucleate in the film. The first Mg and $\text{Mg}_{51}\text{Zn}_{20}$ peak at 32.1° is first clearly seen in the bulk at a temperature of 170°C . In the film the first clear evidence of this peak is at 90°C , although its resolution is poor from $150-170^\circ\text{C}$. The Mg, $\text{Mg}_{51}\text{Zn}_{20}$, and $\text{Ca}_2\text{Mg}_5\text{Zn}_5$ peak at 34.3° is seen at 75°C in the bulk, but not till

115°C in the film. The Mg and Mg₅₁Zn₂₀ peak at 47.7° is seen in both the bulk and film at 170°C.

In the bulk a double peak at 38° and 39° begins to emerge at 125°C, phases which never evolve in the film. The bulk Ca₂Mg₅Zn₅ peaks at 42.3° and 43.7° start to emerge at 165°C and 170°C respectively, but are never seen in the film. The small 57.2° peak at 170°C is also never seen in the film. A final faint peak at 53.3° is seen in the bulk at 175°C, but never in the film. These observations are tabulated in Table 7. The bulk XRD is shown in Figure 11, and the film in Figure 12. Normalised plots allowing for easy identification of differences between the bulk and film are shown in Figures 13, 14, and 15.

Table 7: Main dynamic X-ray diffraction (XRD) peaks for both the bulk and the film. Data shows minor shifting for peaks 3 and 8, large start temperature differences for peaks 1 and 2, and failure of peaks 4 – 7, 9, and 10 to nucleation in the film.

4 DISCUSSION

The use of a 60K DSC heating rate (β) compared to the more commonly used 20K rate [sources] shifts peaks for the bulk $\text{Mg}_{65}\text{Zn}_{30}\text{Ca}_5$ alloy about 8 - 15 degrees higher. This higher β s were used because crystallisation events for the films were difficult to differentiation at the lower β s. Films show little shift to high temperature peaks with increases β s, but large shifts with relaxation. Bulk show the opposite behaviour, larger peaks shifts with higher β s and little shift with relaxation.

The figure shows a plot of DSC fragility for bulk Mg₆₅Zn₃₀Ca₅. The main plot area is empty, with the file path './images/DSC_Fragility_Bulk.png' centered. The plot would typically show heat capacity (Cp) versus temperature (T) for various heating rates (β), with an inset showing the stacked DSC curves and marking the glass transition (Tg) and crystallization (Tx) temperatures for the β = 100 K/min curve.

Figure 2: Bulk Mg₆₅Zn₃₀Ca₅ relaxed at 120 °C for 10 minutes and heated at various heating rates (β s) from 5 to 100K/min. The insert stacks the differential scanning calorimetry (DSC) curves and labels the T_g and T_x s of the $\beta = 100\text{K/min}$ curve.

The figure shows a plot of DSC fragility for film Mg₆₅Zn₃₀Ca₅. The main plot area is empty, with the file path './images/DSC_Fragility_Film.png' centered. The plot would typically show heat capacity (Cp) versus temperature (T) for various heating rates (β), with an inset showing the stacked DSC curves and marking the glass transition (Tg) and crystallization (Tx) temperatures for the β = 100 K/min curve.

Figure 3: Unrelaxed film Mg₆₅Zn₃₀Ca₅ heated at various heating rates (β s) from 15 to 100K/min. The insert stacks the DSC curves and labels the T_g and T_x s of the $\beta = 100\text{K/min}$ curve.
